Additional graph

Original rule:

Each host can only purchase one property per iteration at most.

What would happen if we didn't apply the rule?

Each bar represents a host (there are 100 because the grid is 10x10).

The order is from fewest to most properties.

The majority of hosts have 1 or 2 properties.

Only a few hosts have 3 or 4 properties (the tallest bars at the end).

No one has more than 4 → indicates moderate concentration.

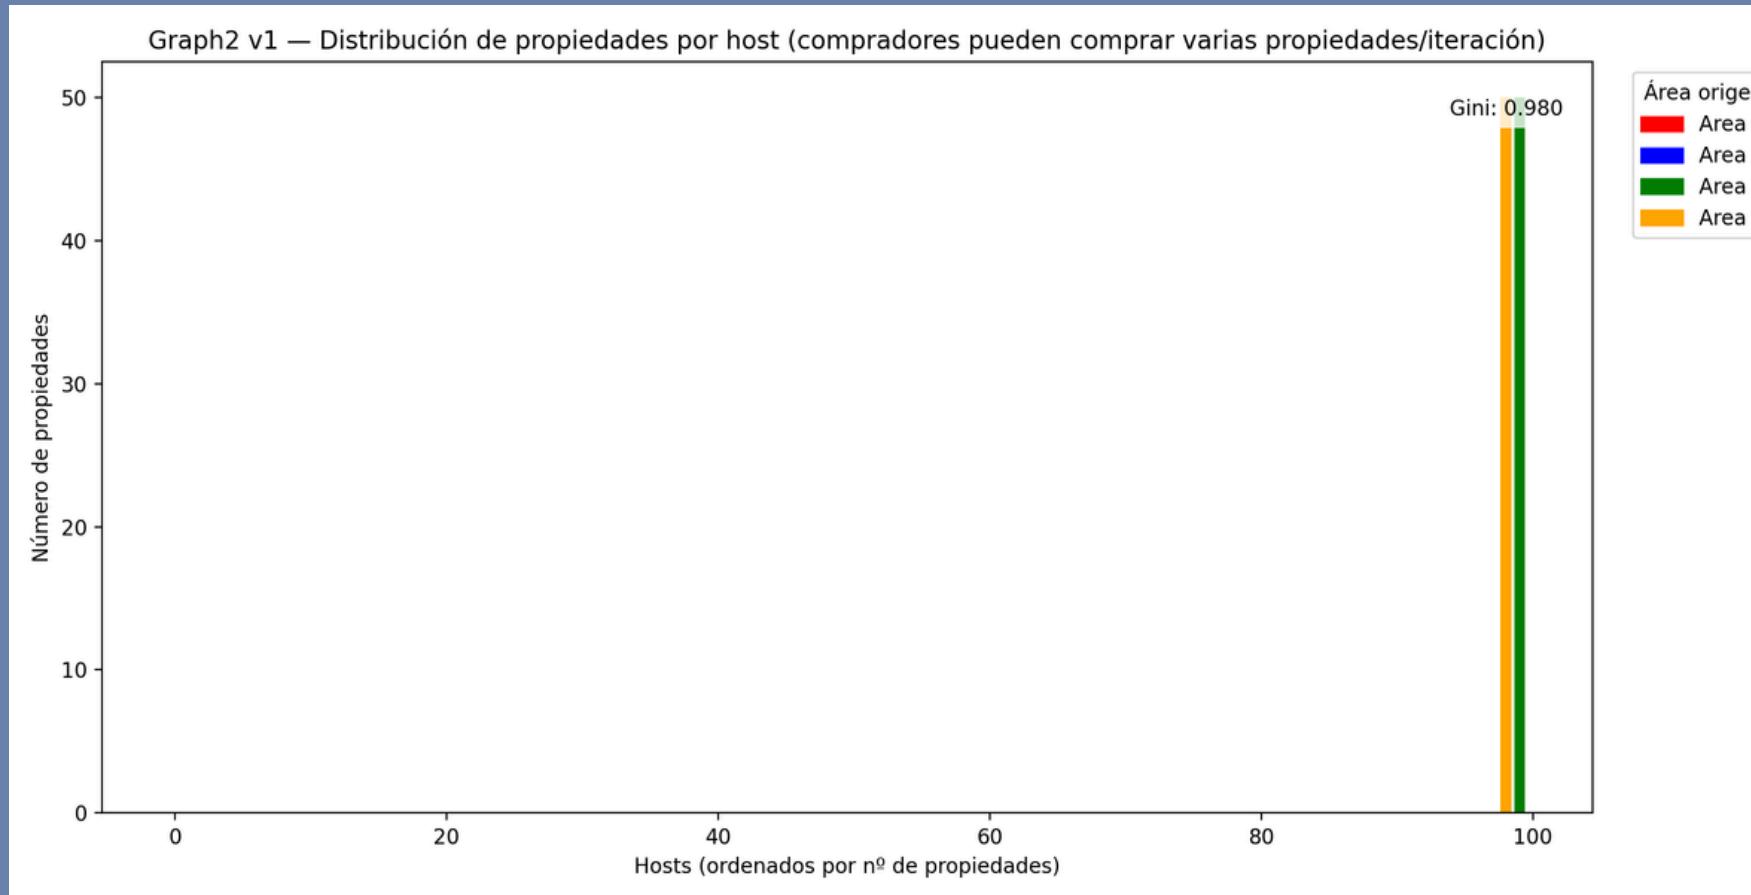

A Gini coefficient of 0.547 indicates a moderate to high concentration, but not an extreme one.

And this fits with our original model, where limiting purchases per iteration curbs hoarding.

Rule Change Snippet

New rule:

Each host can purchase more than one property

```
if not bids:  
    return []  
  
df = pd.DataFrame(bids).sort_values("spread", ascending=False)  
  
sold = set()  
approved = []  
  
for _, b in df.iterrows():  
    pid = b["place_id"]  
    # ya no miramos 'bought' → un buyer puede comprar múltiples properties  
    if pid not in sold:  
        approved.append(b)  
        sold.add(pid)  
  
return approved
```

This graph **shows the distribution of the number of properties per host** after 180 iterations.

All the bars are pointing to the right, which shows us that the market has been divided between **two large monopolists**.

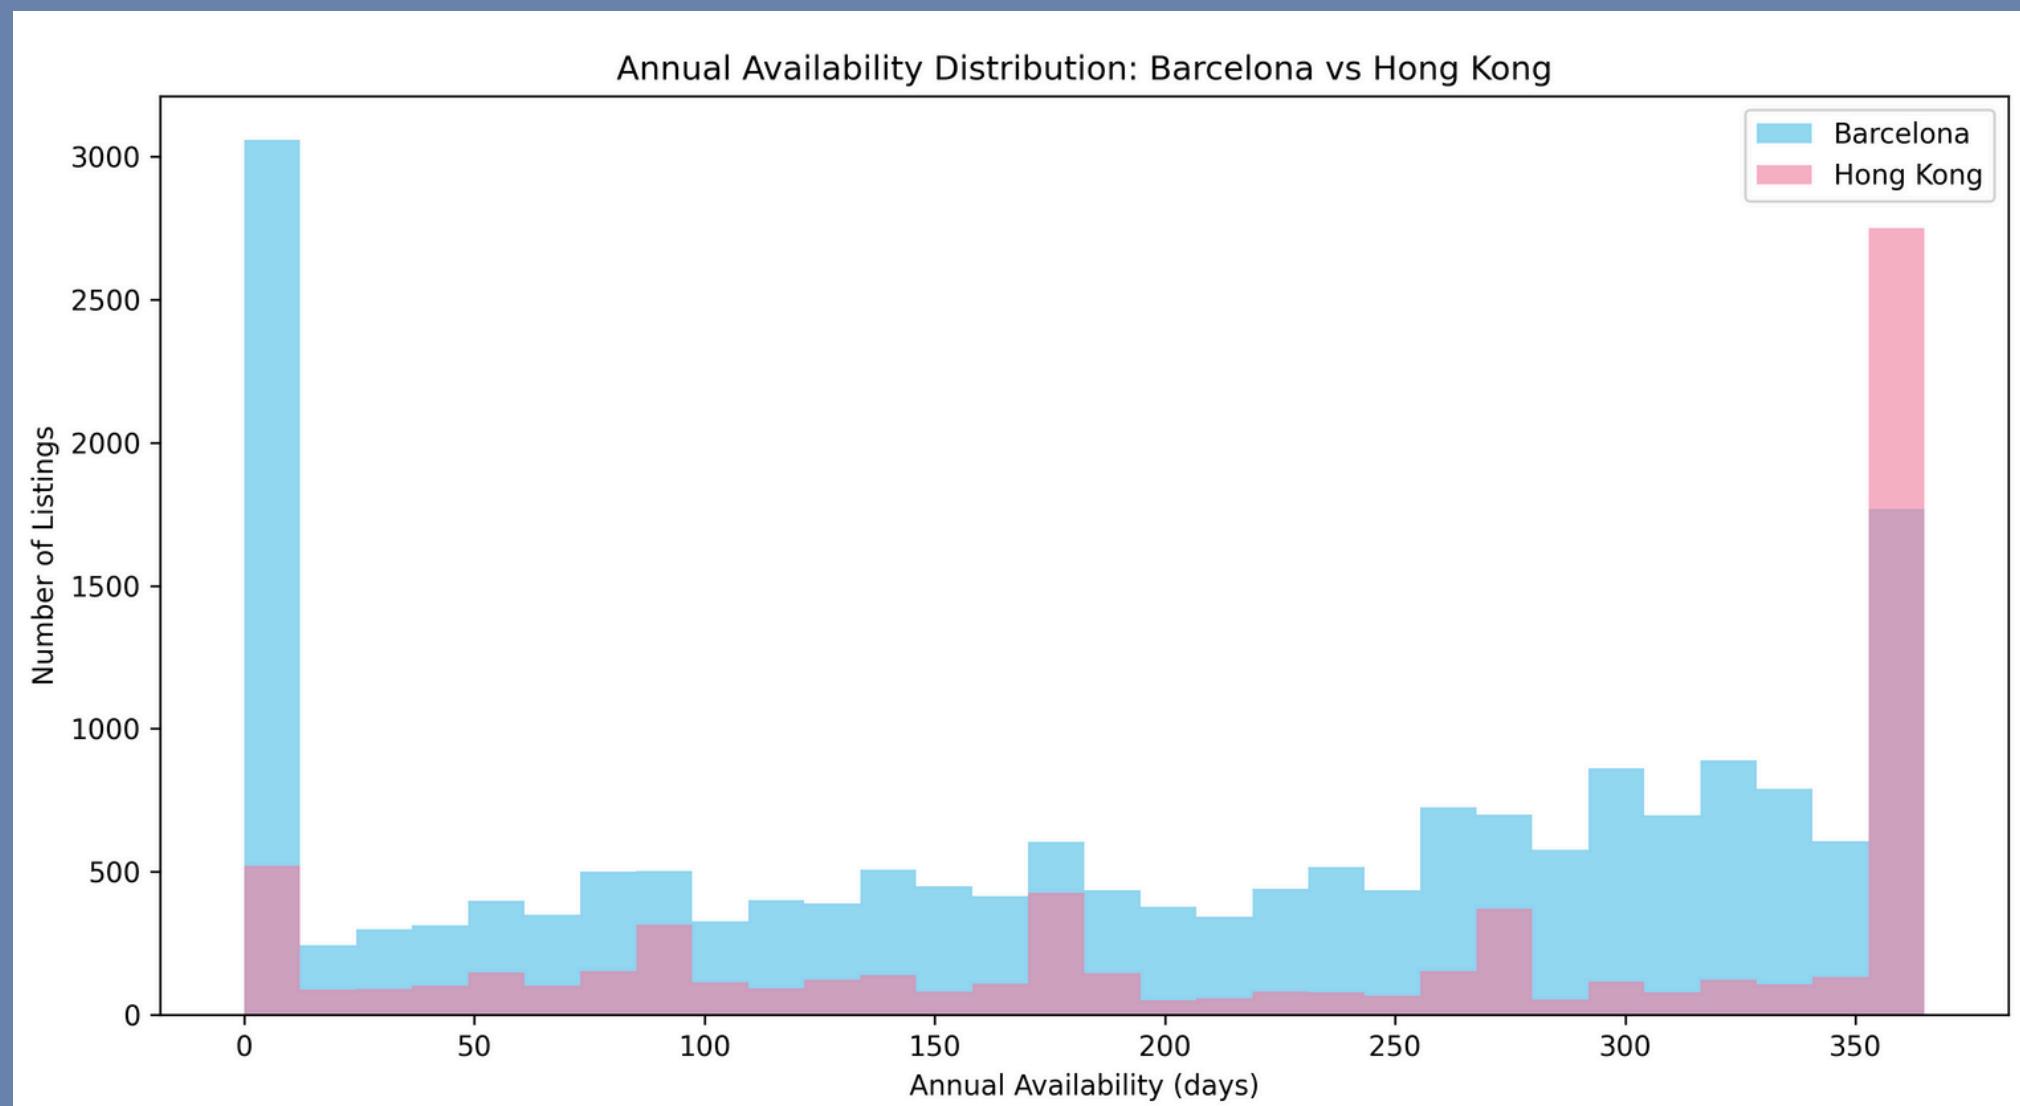

The Gini index is approaching 1, which shows us that there is almost **total inequality**.

What should we do to prevent it?

Having the original rule

This teaches us how important it is to maintain this rule

Analysis - Annual Availability

Barcelona vs Hong Kong

- 0 days = fully booked
 - 365 days = never booked
-
- Hong Knog → low-demand listings
 - Barcelona → more high-demand listings
-
- Market dominated by pros (Barcelona)
 - Many failing listings (Hong Kong)
